Abstract. The AlborEX (Alboran Sea Experiment) consisted of a multi-platform, multi-disciplinary experiment carried out in the Alboran Sea (western Mediterranean Sea) between 25 and 31 May 2014. The observational component of AlborEX aimed to sample the physical and biogeochemical properties of oceanographic features present along an intense frontal zone, with a particular interest in the vertical motions in its vicinity. To this end, the mission included 1 research vessel (66 profiles), 2 underwater gliders (adding up 552 profiles), 3 profiling floats, and 25 surface drifters.

Near real-time ADCP velocities were collected nightly and during the CTD sections. All of the profiling floats acquired temperature and conductivity profiles, while the Provor-bio float also measured oxygen and chlorophyll *a* concentrations, coloured dissolved organic matter, backscattering at 700 nm, downwelling irradiance at 380, 410, and 490 nm, as well as photo-synthetically active radiation (PAR).

In the context of mesoscale and sub-mesoscale interactions, the AlborEX dataset constitutes a particularly valuable source of information to infer mechanisms, evaluate vertical transport, and establish relationships between the thermal and haline structures and the biogeochemical variable evolution, in a region characterised by strong horizontal gradients provoked by the confluence of Atlantic and Mediterranean waters, thanks to its multi-platform, multi-disciplinary nature.

The dataset presented in this paper can be used for the validation of high-resolution numerical models or for data assimilation experiment, thanks to the various scales of processes sampled during the cruise. All the data files that make up the dataset are available in the SOCIB data catalog at <https://doi.org/10.25704/z5y2-qpye> (Pascual et al., 2018). The nutrient concentrations are available at <https://repository.socib.es:8643/repository/entry/show?entryid=07ebf505-bd27-4ae5-aa43-c4d1c85dd500> (last access: 24 December 2018).

1 Introduction

The variety of physical and biological processes occurring in the ocean at different spatial and temporal scales requires a combination of observing and modelling tools in order to properly understand its underlying mechanisms. Hydrodynamical models make it possible to design specific numerical experiments or simulate an idealised situation that can reproduce some of these processes and assess the impacts of climate change. Despite the continuous progress made in modelling (spatial resolution, parameterization, atmospheric coupling, etc.), in situ observations remain an essential yet challenging ingredient when addressing the complexity of the ocean.

To properly capture and understand these small-scale features, one cannot settle for only observations of temperature and salinity profiles acquired at different times and positions, but rather one has to combine the information from diverse sensors and platforms acquiring data at different scales and at the same time, similarly to the approach described in Delaney and Barga (2009). This also follows the recommendation for the Marine Observatory in Crise et al. (2018), especially the co-localisation and synopticity of observations and the multi-platform, adaptive sampling strategy. We will refer to these as multi-platform systems, as opposed to experiments articulated only around the observations made using a research vessel. Further details can be found in Tintoré et al. (2013).

The western Mediterranean Sea is a particularly relevant region for multi-platform experiments, thanks to the wide range of processes taking place, which have been intensively studied since the work of Wüst (1961) on vertical circulation: for example, influence on climate (e.g. Giorgi, 2006; Giorgi and Lionello, 2008; Adloff et al., 2015; Guiot and Cramer, 2016; Rahmstorf, 1998) and sea-level change (e.g. Tsimplis and Rixen, 2002; Bonaduce et al., 2016; Wolff et al., 2018), thermohaline circulation (e.g. Bergamasco and Malanotte-Rizzoli, 2010; Millot, 1987, 1991, 1999; Skliris, 2014; Robinson et al., 2001), water mass formation and convection process (e.g. MEDOC-Group, 1970; Stommel, 1972; Send et al., 1999; Macias et al., 2018), and mesoscale (e.g. Alvarez et al., 1996; Pinot et al., 1995; Pujol and Larnicol, 2005; Sánchez-Román et al., 2017) and sub-mesoscale processes (e.g. Bosse et al., 2015; Damien et al., 2017; Margirier et al., 2017; Testor and Gascard, 2003; Testor et al., 2018). Other recent instances of multi-platform experiments in the Mediterranean Sea were focused on the Northern Current (December 2011, Berta et al., 2018), deep convection in the northwestern Mediterranean sea (July 2012–October 2013, Testor et al., 2018), the Balearic Current system (July and November 2007, April and June 2008, Bouffard et al., 2010) and the coastal current off the west of Ibiza (August 2013, Troupin et al., 2015). Similar studies comparing almost synchronous glider and SARAL/AltiKa altimetric data on selected tracks have also been carried between the Balearic Is-

lands and the Algerian coast (Aulicino et al., 2018; Cotroneo et al., 2016).

Recently, the efforts carried out by data providers and oceanographic data centres through European initiatives such as SeaDataNet (<http://seadatanet.org/>, last access: 24 December 2018) makes the creation and publication of aggregated datasets covering different European regional seas possible, including for the Mediterranean Sea (Simoncelli et al., 2014), upon which hydrographical atlases are being built (e.g. Simoncelli et al., 2016; Iona et al., 2018b). These atlases are particularly useful for the description of the general circulation, the large-scale oceanographic features, or for the assessment of the long-term variability (Iona et al., 2018a). However, their limitation to temperature and salinity variables (as of July 2018) and their characteristic spatial scale prevent them to be employed for the study of sub-mesoscale features.

The AlborEx multi-platform experiment was performed in the Alboran Sea from 25 to 31 May 2014, with the objective of capturing meso- and sub-mesoscale processes and evaluating the interactions between both scales, with a specific focus on the vertical velocities. The observing system, described in the next section, is made up of the *SOCIB* coastal R/V, 2 underwater gliders, 3 profiling floats, and 25 surface drifters, complemented by remote-sensing data (sea surface temperature and chlorophyll concentration). The resulting dataset is particularly rich thanks to the variety of sensors and measured variables concentrated on a relatively small area.

Section 2 strives to summarise the motivations behind the sampling and deployments. The presentation of the available data is the subject of the Sect. 4.

2 The AlborEx mission

The mission took place from 25 May to 31 May 2014 in the Alboran Sea frontal system (Cheney, 1978; Tintoré et al., 1991, see Fig. 1), the scene of the confluence of Atlantic and Mediterranean waters. The mission itself is extensively presented in Ruiz et al. (2015) and the features and processes captured by the observations are discussed in Pascual et al. (2017). Olita et al. (2017) examined the deep chlorophyll maximum variation, combining the bio-physical data from the gliders and the profiling floats. The present paper focuses solely on the description of the original dataset, graphically summarised in Fig. 1.

2.1 General oceanographic context

The definitive sampling area was not firmly decided until a few days before the start of the mission. Prior to the experiment, satellite images of sea surface temperature (SST) and chlorophyll *a* concentration were acquired from the Ocean Color Data server (<https://oceandata.sci.gsfc.nasa.gov/>, last access: 3 August 2018) in order to provide an overview of the surface oceanic features apparent in the Alboran Sea. A well-defined front separating Atlantic and Mediterranean wa-

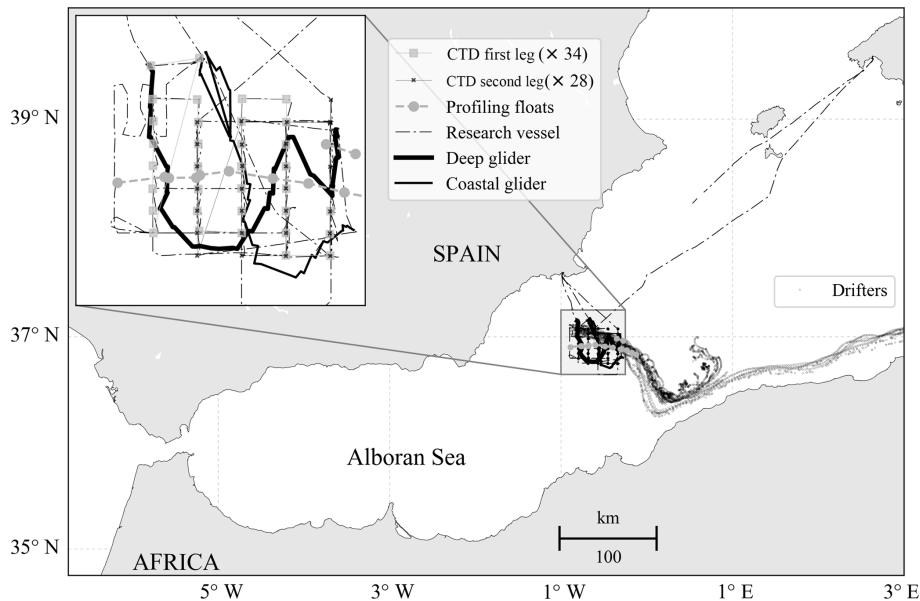

Figure 1. Area of study, positions and trajectories of the main platforms. The close-up view on displays the glider and the CTD measurements.

ters and exhibiting filament-like structures was selected as the study area (see rectangular boxes in Figs. 1 and 2).

The pair of images indicates that the front position slightly changed between 25 and 30 May. An anticyclonic eddy centred around $36^{\circ}30' \text{ N}$, $0^{\circ}30' \text{ W}$, according to altimetry data (not shown), slowly followed an eastward trajectory in the following days. Other SST images during the period of interest (not shown here) displayed different temperature values near the front, yet the front position remains stable.

2.2 Design of the experiment

The deployment of in situ systems was based on the remote-sensing observations described in the previous section. Two high-resolution grids were sampled with the research vessel, covering an approximate region of $40 \text{ km} \times 40 \text{ km}$. At each station, one CTD cast and water samples for chlorophyll concentrations and nutrient analysis were collected. The thermosalinograph observations were also used in order to assess the front position.

One deep glider and one coastal glider were deployed in the same area with the idea to have a butterfly-like track across the front. These idealised trajectories turned out to be impossible considering the strong currents occurring in the region of interest at the time of the mission.

The 25 drifters were released close to the frontal area with the objective of detecting convergence and divergence zones. Their release locations were separated by a few kilometres.

2.3 Data reuse

Three main types of data reuse are foreseen: (i) model validation, (ii) data assimilation (DA), and (iii) planning of similar in situ experiments.

With the increase of spatial resolution in operational models, validation at smaller scales requires high-resolution observations. Remote-sensing measurements such as SST or chlorophyll *a* concentration provide a valuable source of information but are limited to the surface layer. In the case of the present experiment, the position, intensity (gradients), and vertical structure of the front represent challenging features for numerical models, even when data assimilation is applied (Hernandez-Lasheras and Murre, 2018).

The AlborEx dataset can be used for DA experiments, for example, assimilating the CTD measurements in the model and using the glider measurements as an independent observation dataset. The assimilation of glider observations has already been performed in different regions (e.g. Melet et al., 2012; Murre and Chiggiato, 2014; Pan et al., 2014) and has been shown to improve forecast skills. However, the assimilation of high-resolution data is not trivial: the background error covariances tend to smooth the small-scale features present in the observations and the high density of measurements may require the use of super-observations (averaging the observations in the model cells). Another complication arises from the fact that the observational errors are correlated, while data assimilation schemes often assume those errors are not correlated.

Finally, other observing and modelling programs in the Mediterranean Sea can also benefit from the present dataset, for instance the Coherent Lagrangian Pathways from the

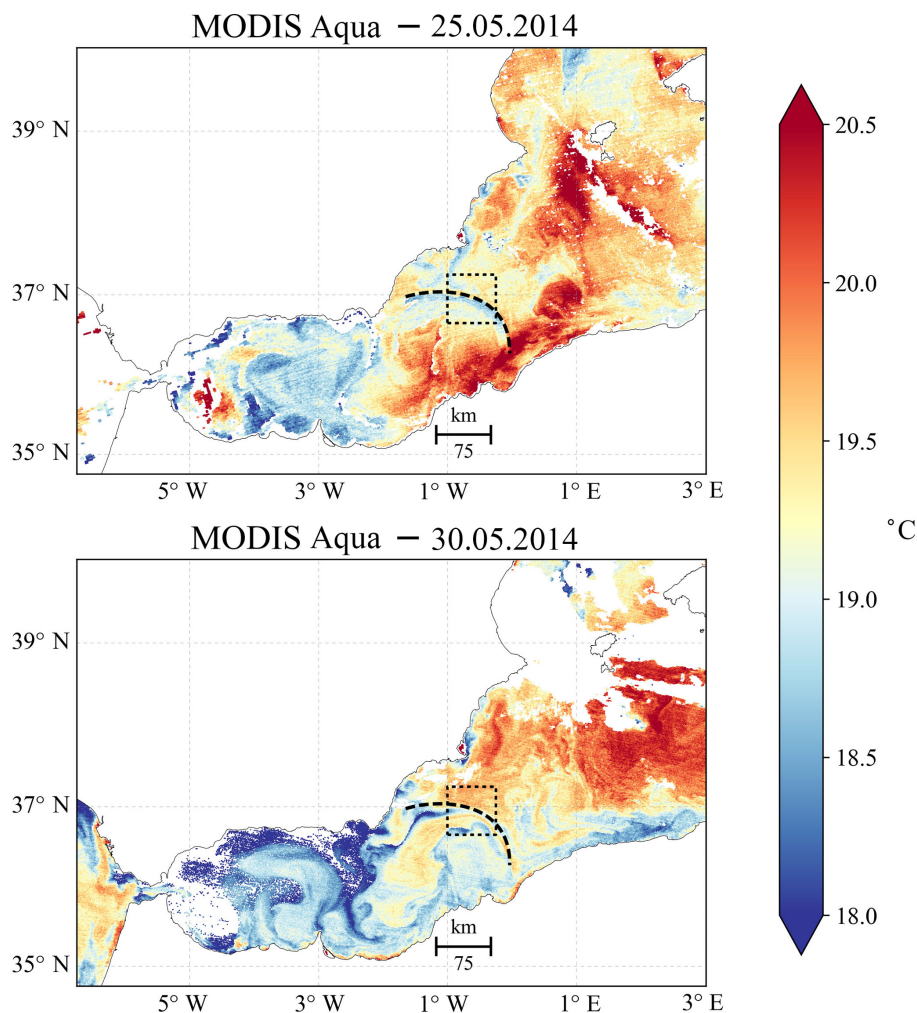

Figure 2. Sea surface temperature in the western Mediterranean Sea from MODIS sensor onboard Aqua satellite corresponding to 25 and 30 May 2014. The dashed black line indicates the approximate position of the front based on the temperature gradient for the period 25–30 May. Level-2, 11 μ m, night-time images were selected. Only pixels with a quality flag equal to 1 (good data) were conserved and represented on the map. The same front position is used in the subsequent figures.

Surface Ocean to Interior (CALYPSO) in the southwestern Mediterranean Sea (Johnston et al., 2018). Similar to AlborEx, CALYPSO strives to study a strong ocean front and the vertical exchanges taking place in the area of interest. For details on the mission objectives; see <https://www.onr.navy.mil/Science-Technology/Departments/Code-32/All-Programs/Atmosphere-Research-322/Physical-Oceanography/CALYPSO-DRI> (last access: 17 December 2018).

2.4 Processing levels

For each of the platforms described in Sect. 2, different processing is performed, with the objective of turning raw data into quality-controlled, standardised data that are directly usable by scientists and experts. Specific conventions for data managed by SOCIB are explained below.

All the data provided by SOCIB are available in different, so-called processing levels, ranging from 0 (raw data) to 2 (gridded data). The files are organised by deployments, a deployment being defined as an event initiated when an instrument is put to sea and finished once the instrument is recovered from sea. Table 1 summarises the deployments performed during the experiment and the available processing levels.

Level 0 (L0). This is the level closest to the original measurements, as it is designed to contain exactly the same data as the raw files provided by the instruments. The goal is to deliver a single, standardised netCDF file, instead of one or several files in a platform-dependent format.

Level 1 (L1). In this level, additional variables are derived from the existing ones (e.g. salinity, potential tempera-

Table 1. Characteristics of the instrument deployments in AlborEx.

Instruments	Number of deployments	Initial time	Final time	Processing levels		
				L0	L1	L2

ADCP on board R/V	1	25 May 2014	2 May 2014	✓	✓	
CTD	1 (66 stations)	25 May 2014	2 May 2014	✓	✓	
Gliders	2	25 May 2014	30 May 2014	✓	✓	✓
Surface drifters	25	25 May 2014	beyond the experiment	✓	✓	
Profiling floats	3	25 May 2014	beyond the experiment	✓	✓	

ture). The attributes corresponding to each variable are stored in the netCDF file, with details of any modifications. Unit conversion is also applied if necessary.

Level 1 corrected (L1_corr). This level is only available for the CTD. A corrective factor is obtained by a linear regression between the salinity measured by the CTD and that measured by the salinometer. The files corresponding to the processing levels contain new variables of conductivity and salinity, to which the correction was applied. Additional metadata regarding the correction are also provided in the file.

Level 2 (L2). This level is only available for the gliders. It consists of regular, homogeneous, and instantaneous profiles obtained by gridding the L1 data. In other words, 3-dimensional trajectories are transformed into a set of instantaneous, homogeneous, regular profiles. For the spatial and temporal coordinates, the new coordinates of the profiles are computed as the mean values of the cast readings. For the variables, a binning is performed, taking the mean values of readings of depth intervals centred at selected depth levels. By default, the vertical resolution (or bin size) is set to 1 m. This level was created mostly for visualisation purposes.

The glider data require specific processing to ingest and convert the raw data files produced by the coastal and deep units. This is done within a toolbox designed for this purpose and extensively described in Troupin et al. (2016), the capabilities of which include metadata aggregation, data download, advanced data processing, and the generation of data products and figures. Of particular interest is the application of a thermal-lag correction for unpumped Sea-Bird CTD sensors (Garau et al., 2011), which improves the quality of the glider data.

2.5 Quality control

Automated data QC is part of the processing routine of the SOCIB Data Center: most of the datasets provided with this paper come with a set of flags that reflect the quality of the measurements, based on different tests regarding the range

Table 2. Quality control flags.

Code	Meaning
0	No QC was performed
1	Good data
2	Probably good data
3	Probably bad data
4	Bad data
6	Spike
8	Interpolated data
9	Missing data

of measurements, the presence of spike, the displacement of the platform, and the correctness of the metadata.

The QC is based on existing standards for most of the platforms. They are extensively described in the Quality Information Document (SOCIB Data Center, 2018). The description platform by platform is provided in the next Section.

2.5.1 Quality flags

The flags used for the data are described in Table 2.

2.5.2 QC tests

The main tests performed on the data are as follows.

Range. Depending on the variable considered, low and high thresholds are assigned. First there is a global range: if the measured values fall outside, then the flag is set to 4 (bad data). Then a regional range test is applied: the measurements outside this range are assigned the flag 2 (probably good).

Spike. This test consists of checking the difference between sequential measurements (i.e. not measured at the same time). For the j -th measurement

$$\text{spike} = \left| V_j - \frac{V_{j+1} + V_{j-1}}{2} \right| - \left| \frac{V_{j+1} - V_{j-1}}{2} \right|.$$

When the spike value is above the threshold (depending on the variable), the flag is set to 6.

Gradient. This is computed for the variables along different coordinates (horizontal, depth, time).

Stationarity. This aims to check if measurements exhibit some variability over a period of time, by computing the difference between the extremal values over that period.

It is worth mentioning the tests described above are not yet applied on the glider data, since their processing is done outside of the general SOCIB processing chain, but the tests have been implemented in the glider toolbox (Troupin et al., 2016, and available at: https://github.com/socib/glider_toolbox; last access: 24 December 2018) and will be made operational once they have been properly tested and validated.

As the new files will not be available before a full reprocessing of all the historical missions, the decision was taken to provide the data files in their current state. A new version will be uploaded as soon as the processing has been performed.

3 In situ observations

Whereas the remote sensing measurements helped in the mission design and front detection, in situ observations were essential to fulfill the mission objectives. The different platforms deployed for the data collection are presented below.

3.1 Research vessel

The *SOCIB* coastal research vessel (R/V) was used to sample the area with vertical profiles acquired through the CTD. Two distinct CTD legs were performed on a $10\text{ km} \times 5\text{ km}$ resolution grid, as depicted in Fig. 3. The first survey was run from 26 to 27 May and consisted of 34 casts along five meridional legs. The second survey took place from 29 to 30 May and was made up of 28 casts. The casts from both surveys were performed at similar locations in order to allow for detecting changes between the two periods. On average the profiles reached a maximal depth of approximately 600 m.

The distinct water properties on both sides of the front are evidenced by the T–S diagrams in Fig. 4, where the colours represent the fluorescence. The salinity range north of the front is roughly between 38 and 38.5, with the exception of a few measurements, and confirms the nature of the Mediterranean water mass. The fluorescence maximum appears between 14 and 15 °C. South of the front, the salinity range is wider while the temperature values are similar to the north.

In addition to the CTDs, the R/V thermosalinograph continuously acquired temperature and conductivity along the ship track, from which near-surface salinity is derived (Fig. 5). The R/V weather station acquired air temperature, pressure, and wind speed and direction during the whole duration of the mission. Direct measurements of currents were performed with an acoustic Doppler current profiler and are presented in Sect. 3.5.

Figure 3. The CTD casts were organised into five legs that crossed the front and were repeated over two periods, at the beginning and the end of the mission.

3.1.1 Configuration

The CTD rosette was equipped with the following instruments:

- a Sea-Bird SBE 911Plus, two conductivity and temperature sensors, and one pressure sensor units;
- a SBE 43 oxygen sensor; and
- a Seapoint [FTU] fluorescence and turbidity sensor.

The GEONICA METEODATA 2000 weather station measured the following variables: air pressure, temperature, humidity, and wind speed and direction, with a resolution of 10 min. The continuous, near-surface measurements of temperature and salinity are provided by a SeaBird SBE21 thermosalinograph.

3.1.2 Quality control

The general checks described in Sect. 2.5.2 (i.e. ranges, spike, gradient and stationarity) are applied on the temperature, salinity, conductivity, and turbidity. The threshold values are detailed in the corresponding tables in the QC procedure document (SOCIB Data Center, 2018). As mentioned in Sect. 2.4, netCDF files with a correction applied on the salinity and conductivity are also provided (L1_corr).

3.2 Gliders

To collect measurements addressing the sub-mesoscale, two gliders were deployed on 25 May inside the study area. The

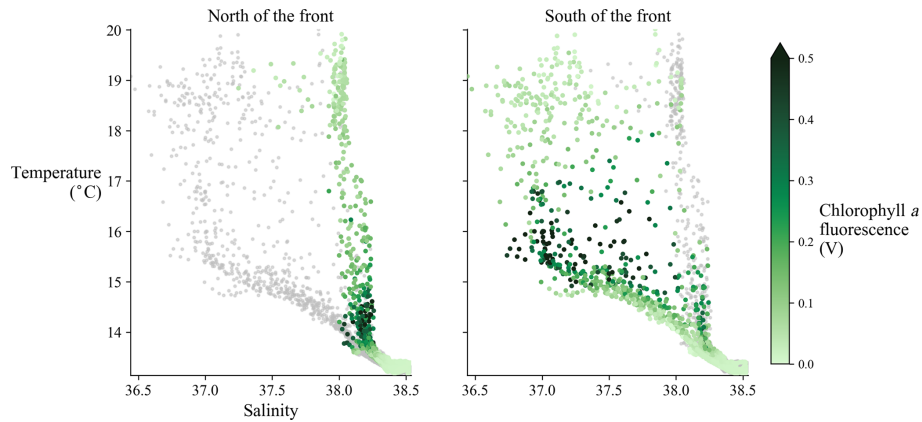

Figure 4. The T-S diagrams are shown separately for the casts located north and south of the front (broad, dashed line).

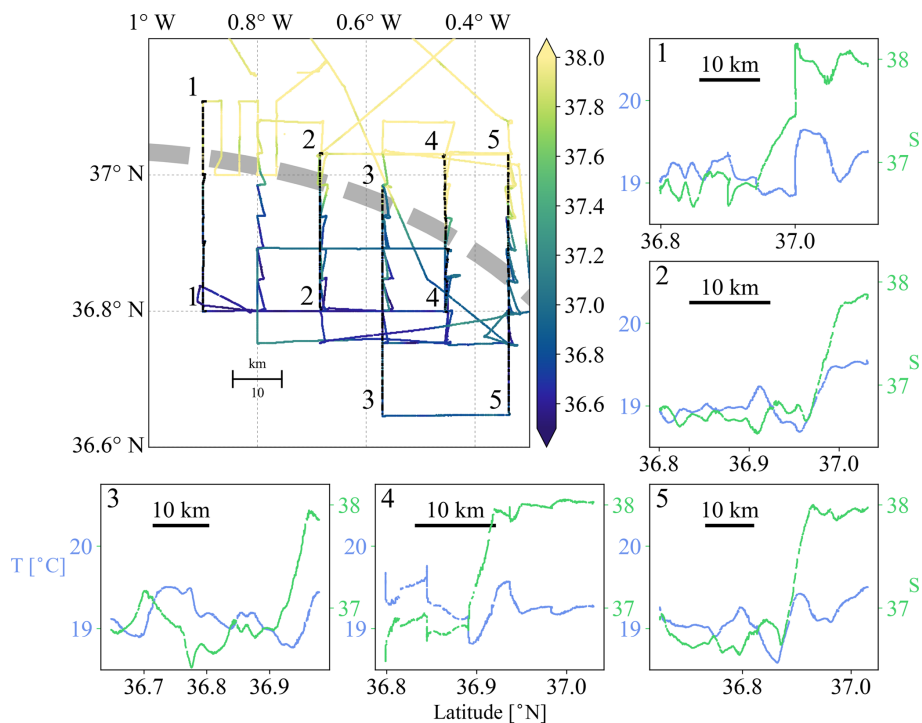

Figure 5. The near-surface salinity (coloured dots) measured by the thermosalinograph is evidence of strong horizontal gradients, in agreement with the front position, as obtained using the SST (broad, dashed line). The five subplots depict the temperature and salinity along selected meridional tracks.

coastal glider carried out measurements up to a 200 m depth and the deep glider up to 500 m. The horizontal resolution was about 0.5 km for the shallow glider and 1 km for the deep glider. The initial sampling strategy consisted of two 50 km long, meridional tracks, 10 km away from each other, and to repeat these tracks up to 4 times during the experiment. However, due to the strong zonal currents in the frontal zone, different tracks (Fig. 6) crossing the front several times were made instead.

On 25 May at 19:24 (UTC), the deep glider payload suffered an issue with the data-logging software, resulting in no

data acquisition during a few hours, during which the problem was being fixed. After this event, the data acquisition could be resumed on 26 May at 08:50 (UTC).

The mean vertical separation between two consecutive measurements is around 16 cm. Figure 7 displays the temperature and salinity sections obtained with the two vehicles. The high density of measurements makes it possible to distinguish small-scale features on both sides of the front, such as strong lateral gradients, subduction, or filament structures.

The gliders follow a 3-dimensional trajectory in the water column, but for some specific usages it is sometimes more

Figure 6. Deployment positions and trajectories of the gliders. Different time instances separated by 1 day are indicated on the tracks to provide a temporal dimension.

convenient to have the glider data as if they were a series of vertical profiles. To do so, a binning is applied to the original data, leading to the L2 data, as described in Sect. 2.4.

3.2.1 Configuration

The information concerning the two gliders is summarised in Table 3. Due to safety concerns, both the deep and coastal gliders had their surfacing limited: the deep glider came to the surface one in every three profiles, while the coastal gliders came out one in every 10 profiles. While this strategy does not appear optimal from a scientific point of view (loss of measurements near the surface, meaning of the depth-averaged currents), the priority was set on the glider integrity.

3.2.2 Quality control

Before deployment, the glider compass was calibrated following Merkelbach et al. (2008). The thermal-lag happening on the unpumped Sea-Bird CTD sensors installed on the deep and coastal gliders was corrected using the procedure described in Garau et al. (2011).

The checks not yet applied but planned for the next release of the Glider toolbox include the removal of *NaN* values; the detection of impossible dates or locations; valid ranges (depending on depth) for the variables, spikes, and gradients; and constant values over a large range of depths in the profiles. The tests performed that showed a constant value check proved useful for conductivity (and hence density and salinity). A new version of the present dataset will be released once these new checks are made operational.

Finally, oxygen concentration measurements (not shown here) seem to exhibit a lag. According to Bittig et al. (2014), this issue is also related to the time response of oxygen optodes. As far as we know, there is not yet an agreement from the community on how to correct this lag, this is why the data are kept as they are in the present version, though we do not discard the possibility that an improvement in the glider toolbox could address this specific issue.

3.3 Surface drifters

On 25 May, 25 Surface Velocity Program (SVP, Lumpkin and Pazos, 2007) drifters were deployed in the frontal area in a tight square pattern, with a mean distance between neighbour drifters of around 3 km. In the Mediterranean Sea, they have been shown to provide information on surface dynamics, ranging from basin scale to mesoscale features or coastal currents (Poulain et al., 2013). Almost all the drifters were equipped with a thermistor on the lower part of the buoy to measure sea water temperature.

A total of 11 out of the 25 drifters, especially those deployed more to the south, were captured by the intense Algerian Current and followed a trajectory along the coast to a longitude about 5°30' E. The other drifters were deflected northward when they reached about 0°30' E, then veered northwestward or eastward and described cyclonic and anticyclonic trajectories, respectively. All the drifters moved along the front position (deduced from the SST images), until they encounter the Algerian Current (Fig. 8).

On average, the temporal sampling resolution is close to 1 h, except for two drifters for which the intervals are 4 and 5 h. The velocities are directly computed from the successive positions and highlight the strength of the Algerian Current with velocities in the order of 1 m s⁻¹ (Fig. 9).

3.3.1 Configuration

The drifters deployed during the experiment are the World Ocean Circulation Experiment SVP mini-drifters. These drifters are made up of a surface buoy that includes a transmitter to relay data and a thermistor to measure the water temperature near the surface; the buoy is tethered to a holey-sock drogue centred at 15 m depth. The possible loss of the drogue is controlled with a tension sensor located below the surface buoy.

A total of 15 drifters were manufactured by Pacific Gyre and 10 by Data Buoy instrumentation (DBi). All the drifters contributed to the Mediterranean Surface Velocity Programme (MedSVP).

3.3.2 Quality control

Tests are applied on the position (i.e. on land), velocity and temperature records (valid ranges and spikes). Checking the platform speed is particularly relevant, as abnormally high

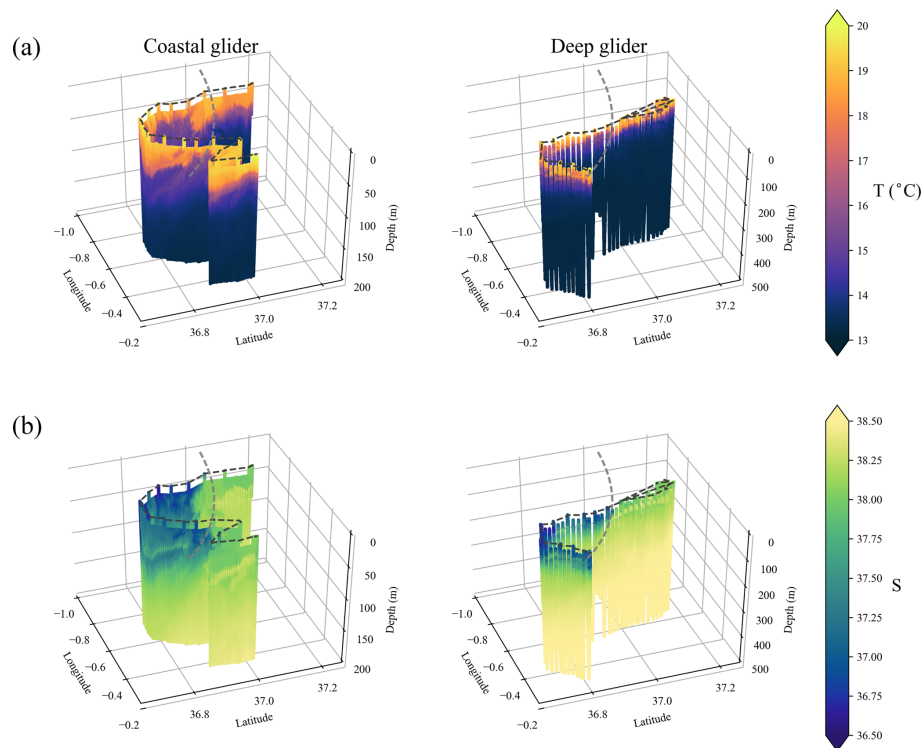

Figure 7. Temperature (a) and salinity (b) measured by the two gliders. The approximate front position at the surface is shown as a dashed grey line.

values are intermittently encountered. See the SOCIB Data Center (2018) for the threshold values used in the checks. In addition, the method developed by Rio (2012) is used to improve the accuracy of the drogue presence from wind slip-page (Menna et al., 2018).

3.4 Profiling floats

Three profiling floats were deployed in the same zone as the drifters on 2 May (see Table 4). Their configuration depends on the float type: the Arvor-C has higher temporal resolution (hours) and does not go much deeper than 400 m. The A3 and Provor-bio platforms are usually set to have a cycle length

between 1 and 5 days, with the Provor-bio platform reaching maximal depth in the order of 1000 m. The floats constitute an essential tool in order to monitor the mesoscale (Sánchez-Román et al., 2017). The trajectories (Fig. 10) clearly show that profiles were acquired in the frontal area, before the floats were eventually captured by the Algerian Current.

The Arvor-C trajectory closely follows the front position until a latitude of 36°30' N, accounting for 455 profiles in the vicinity of the front. This is probably due to its configuration: its high frequency temporal sampling makes it possible to spend more time in the near-surface layer and hence the float follows the front better than the two other float types. Its last

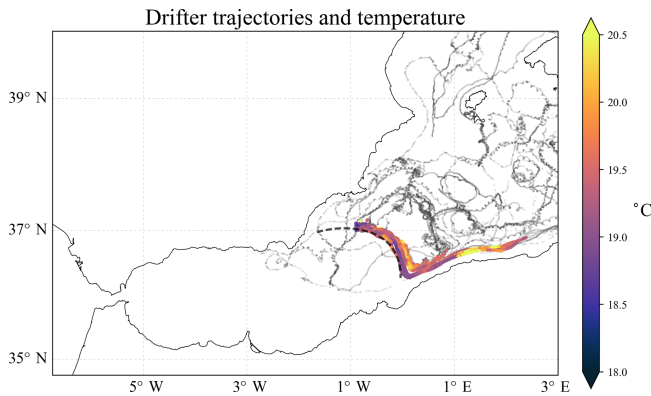

Figure 8. Surface drifter trajectories. For the sake of simplicity and clarity, the temperature, when available, is only shown for the duration of the AlborEx mission (25–31 May 2014).

profile was taken on 14 June 2014, at an approximate location of 36°15' N, 4° E, then it drifted at the surface.

3.4.1 Configuration

The three floats provided temperature and salinity profiles thanks to the Sea-Bird CTD. In addition to these variables, the PROVBIO (PROVOR CTS4) platform measured biochemical and optical properties: coloured dissolved organic matter (CDOM), chlorophyll *a* concentration, backscattering (650 nm), dissolved oxygen concentration and downwelling irradiance (380, 410, 490 nm), and photosynthetically active radiation (PAR). Table 4 reports the main deployment characteristics. All the floats are manufactured by NKE (Hennebont, France). The profiles were performed around noon, local time, and were used in combination with the glider measurements to study the deep chlorophyll maximum (DCM) across the front (Olita et al., 2017).

3.5 Current profiler

The Vessel Mounted-Acoustic Doppler Current Meter Profiler (VM-ADCP) acquired velocity profiles approximately every 2 min during night-time (22:00–06:00 UTC) at a speed of 10 knots and during the CTD surveys (see Fig. 3). The measurement accuracy is in the order of 0.01 m s^{-1} . The measurements were vertically averaged over 8 m depth bins.

The velocities exhibit a dominant eastward current with speed locally larger than 1 m s^{-1} and a signal that is clearly visible in the first 100 m of the water column. The velocity field is illustrated in Fig. 11, where each velocity vector is shown as a bar with a colour depending on the intensity. The vertical structure is also displayed along with the front position.

3.5.1 Configuration

The current profiler is an Ocean Surveyor ADCP, manufactured by Teledyne RD Instruments and operating at a frequency of 150 kHz. This instrument was configured with 8 m depth bins and a total of 50 bins. Final velocity profiles were averaged in 10 min intervals. The transducer depth is approximately 2 m.

The position and behaviour (heading, pitch, and roll) of the research vessel is obtained with an Ashtec 3-D GPS 800 ADU positioning system that provides geographical positions with a 10–20 cm accuracy and heading, pitch, and roll with an accuracy on the order of 1° . The instrument was calibrated to correct the misalignment angle and scaling factor. The technical report referring to this platform is available in Annex II of Ruiz et al. (2015).

3.5.2 Quality checks

The vessel's velocity is 1 or 2 orders of magnitudes greater than the currents that have to be measured, hence this type of current measurements requires a careful processing in order to get meaningful velocities from the raw signal. The QC procedure for the VM-ADCP is complex as it involves tests on more than 40 technical and geophysical variables (SOCIB Data Center, 2018). The different tests are based on the technical reports of Cowley et al. (2009) and Bender and Di-Marco (2009), which are aimed primarily at ADCP mounted on moorings. The procedure can be summarised as follows.

1. *Technical variables.* Valid ranges are checked for each of these variables: if the measurement is outside the range, the QF is set to 4 (bad data). Examples of technical variables are bottom track depth, sea water noise amplitude, and correlation magnitude.
2. *Vessel behaviour.* Vessel pitch, roll, and orientation angles are checked and QF are assigned based on specific ranges. In addition, the vessel velocity is checked and anomalously high values are also flagged as bad.
3. *Velocities.* Valid ranges are provided for the computed current velocities: up to 2 m s^{-1} , velocities are considered as good; between 2 and 3 m s^{-1} , probably good, and above 3 m s^{-1} , bad.

The application of all of these tests led to Fig 12, which illustrates the QF during the whole mission. The three main periods during which the ADCP was turned off are shown as grey areas. In addition, no measurements are available in the first metres of the water column, due to the position of the ADCP on the ship, at a depth of approximately 2 m.

Overall, the quality of the data tends to deteriorate when the depth increases, as reflected by the bad and missing values. In the first 200 m, about 95 % of the measurements are considered as good. Below 200 m, the ratio drops to 57 % with more than 21 % of missing values. Note that the flags 5, 7 and 8 were not used in this case but kept in the plot.

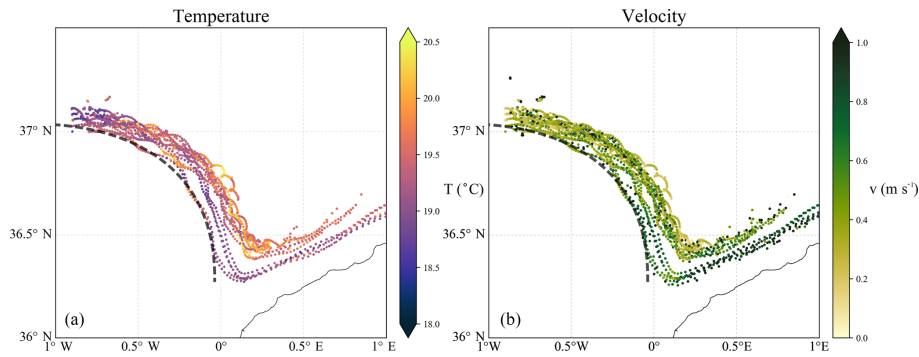

Figure 9. Drifter temperature (a) and velocity (b) in the area of study.

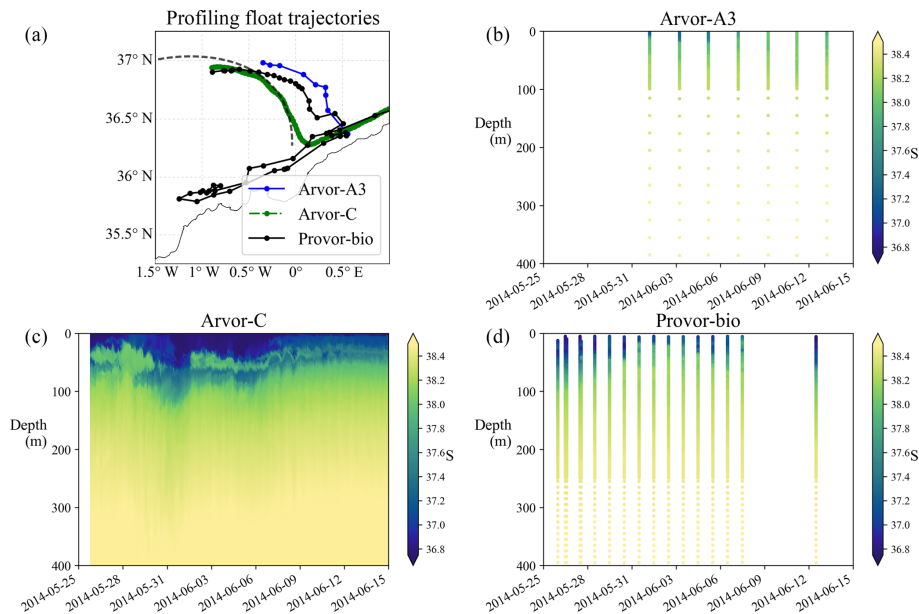

Figure 10. Profiling float trajectories and salinity from 25 May to 15 June 2014.

3.6 Nutrients

Samples for nutrient analysis were collected in triplicate from CTD Niskin bottles and immediately frozen for subsequent analysis at the laboratory. Concentrations of dissolved nutrients (Nitrite: NO_2^- , Nitrate: NO_3^- , and Phosphate: PO_4^{3-}) were determined with an autoanalyser (Alliance Futura) using colourimetric techniques (Grasshoff et al., 1983). The accuracy of the analysis was established using the Coastal Seawater Reference Material for Nutrients (MOOS-1, NRCCNRC), resulting in recoveries of 97 %, 95 %, and 100 % for NO_2^- , NO_3^- , and PO_4^{3-} , respectively. Detection limits were NO_2^- : $0.005 \mu\text{M}$, NO_3^- : $0.1 \mu\text{M}$, and PO_4^{3-} : $0.1 \mu\text{M}$.

4 Description of the database

The AlborEx mission generated a large amount of data in a region sparsely sampled in the past. The synergy between low-resolution (CTD, drifters, floats) and high-resolution data (ADCP, gliders) makes this dataset unique for the study of sub-mesoscale processes in the Mediterranean Sea. Moreover its multidisciplinary nature makes it suitable to study the interactions between the physical conditions and the biogeochemical variables.

4.1 File format and organisation

The original data files (i.e. obtained directly from the sensors and with a format depending on the manufacturer) are converted to the Network Common Data Form (netCDF, <https://doi.org/http://doi.org/10.5065/D6H70CW6>, last access: 3 August 2018), an Open Geospatial Consortium

Table 4. Characteristics of the profiling floats.

Platform	Final date	Maximal depth (m)	Cycle length	No. of profiles	
				Mission	Total
ARVOR-A3	17 Jun 2014	2000	1 day	3	12
ARVOR-C	17 Jun 2014	400	1.5 h	144	2507
PROVOR CTS4	24 Apr 2015	1000	1 day until 7 Jun, then 5 days	9	71

**Figure 11.** Velocity field obtained with the ADCP at a 40 m depth (a) and sections of zonal velocity on 26 May (S1, b) and 27 May (S2, c). The locations of the sections are indicated by dashed rectangles on the map. Only data with a quality flag equal to 1 (good data) are represented.

(OGC) standard widely adopted in atmospheric and oceanic sciences. Each file contains the measurements acquired by the sensors as well the metadata (mission name, principal investigator, etc.). The structure of the files follows the Climate and Forecast (CF) conventions (Domenico and Nativi, 2013) and are based on the model of OceanSITES (Send et al., 2010).

4.2 File naming

In order to keep the file names consistent with the original database, it was decided to keep the same file names as those assigned by the SOCIB Data Center. As an example, we deconstruct one file name – dep0007_socib-rv_scb-sbe9002_L1_2014-05-25 – into its different parts below.

dep0007 indicates the number of the deployment, where deployment is the equivalent to the start of a mission or survey with a given platform. The deployment ends

when the mission is over or if the platform stops acquiring data.

socib-rv is the code for the platform, in this case the *SOCIB* coastal research vessel.

scb-sbe9002 is the instrument identifier, here the CTD SeaBird 9Plus. Note that the instrument is described in the metadata of the netCDF file.

L1 is the processing level (see Sect. 2.4).

2014-05-25 is the deployment date (year-month-day).

Now the general naming is defined, Table 5 lists the different files made available in the dataset.

4.3 Data reading and visualisation

The standard format (netCDF) in which the data files are written makes the reading and visualisation straightforward. A variety of software tools such as ncview, ncBrowse,

Figure 12. Quality flags for the velocity measurements. The areas marked with a \times are those during which the VM-ADCP was not acquiring measurements.

*** in the file names stands for 3 digits.

or Panoply are designed to visualise gridded fields. Here the data provided consist of trajectories (surface or 3-dimensional), profiles, and trajectory-profiles, which can be easily read using the netCDF library in different languages (Table 6).

Examples of reading and plotting functions, written in Python, are also provided (Troupin, 2018). They allow users or readers to get the data from the files and reproduce the same figures as in the paper, constituting a good starting point to carry out further specific analysis.

When accessing the data catalog, users are provided a list of in-house visualisation tools designed to offer quick visualisation of the file content. The visualisation tools depend on the type of data: JWebChart is used for time series; Dapp displays the trajectory of a moving platform on a map; the profile-viewer allows the user to select locations on the map and view the corresponding profiles.

5 Code and data availability

Following SOCIB general policy, the data are made available as netCDF files through the SOCIB Thematic Real-time Environmental Distributed Data Services (THREDDS) data server, a standard way to distribute metadata and data using a variety of remote data access protocols such as OPeNDAP, Web Map Service (WMS), or direct HTTP access. In addition, the whole AlborEx dataset has been assigned a digital object identifier (DOI) to make it uniquely citable. The most recent version of the dataset is accessible from <http://doi.org/10.25704/z5y2-qpye> (last access: 24 December 2018; Pascual et al., 2018), and the nutrient data, in the process of being included in the catalog, are available at <https://doi.org/10.5281/zenodo.2384855> (last access: 24 December 2018; Troupin, 2018).

Upgrades will be performed periodically with the implementation of fresh or better QCs on sensors such as the ADCP, CTD, or gliders. The new releases will be available using the same Zenodo identifier, but will be assigned a dif-

MATLAB	Native support since version R2010b

ferent version number, each version having its own DOI. Files not available at the time of the writing will also be appended to the original database.

Concerning the improvement of the quality control, it is worth mentioning the new tests that will be implemented in the SOCIB Glider Toolbox (Troupin et al., 2016).

The checks performed on the ADCP velocities involve a set of parameters that can also be fine-tuned to improve the relevance of the quality flags. Nevertheless, noticeable changes are not expected with respect to the quality flags displayed in Fig. 12.

Finally, the quality of the CTD and the glider profiles can be improved by using the salinity measurements of water samples collected during the mission. This type of correction might not be essential for the study of mesoscale processes but is crucial when one is focused on long-term studies and when a drift can be observed in the salinity measurements.

A set of programs in Python to read the files and represent their content, as in the figures presented through the paper, are available at <https://github.com/ctroupin/AlborEX-Data> (last access: 24 December 2018). The programs are written in the form of documented Jupyter notebooks, a web application that combines code fragments, equations, graphics, and explanatory text (<http://jupyter.org/>, last access: 14 August 2018), so that they can be run step by step. The figure's colourmaps were produced using the `cmocean` module (Thyng et al., 2016).

6 Conclusions and perspectives

The AlborEx observations acquired in May 2014 constitute a unique observational dataset that captured mesoscale and sub-mesoscale features in a particularly energetic frontal zone in the western Mediterranean Sea. The potential uses of the dataset can be separated into the following different topics.

- *Hydrodynamic model validation.* With their increasing resolution, models are becoming able to properly reproduce small-scale structures, but the correct timing and location of these features remain a challenging topic.

- *High-resolution remote-sensing data validation.* High-quality in situ measurements of the sea surface are essential for the validation of operational products such as SST or Ocean Color.
- *Study of mechanisms.* The Mediterranean Sea is often referred to as a laboratory for oceanography and the Alboran Sea in particular is a stage for intense processes of mixing, subduction, and instability.
- *Assessment of mechanisms responsible for intense vertical motions.*

The version of the dataset described in the present paper contains files that have been processed and standardised so that they are directly usable by scientists without having to perform unit or format conversions from the manufacturer's raw data files.

Updates will be performed when new files or new versions of the existing files are made available.

Author contributions. CT prepared the figures and the first version of the manuscript. AP and SR edited the manuscript. JGF and MAR lead the data management and the creation of a DOI in Datacite. CM implemented the processing of the ADCP data. GN helped with the processing of the drifters and profiling floats. EA and AT processed and provided the biochemical data. IR finalised the QC documentation.

Competing interests. The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Disclaimer. The authors do not accept any liability for the correctness and appropriate interpretation of the data or their suitability for any use.

Acknowledgements. We wish to thank the three anonymous reviewers for their constructive comments and the extensive check of the data files. AlborEx was conducted in the framework of PERSEUS EU-funded project (grant agreement no. 287600).

Glider operations were partially funded by the JERICO FP7 project. Ananda Pascual acknowledges support from the Spanish National Research Program (E-MOTION/CTM2012-31014 and PRE-SWOT/CTM2016-78607-P). Simon Ruiz and Ananda Pascual are also supported by the Copernicus Marine Environment Monitoring Service (CMEMS) MedSUB project. Antonio Olita was supported by the JERICO-TNA program, through the FRIPP (FRontal Dynamics Influencing Primary Production) project. The profiling floats and some drifters were contributed by the Argo-Italy program. The proceedings of such an ambitious mission would not have been possible without the involvement of numerous staff both at sea and on land: Ana Massanet, Margarita Palmer, Irene Lizaran, Carlos Castilla, Pau Balaguer, Milena Menna, Kristian Sebastián, Sebastián Lora, and Antonio Bussani.
